Abstract

Background: Candida spp. are known to be the most common fungal pathogens isolated from blood cultures of neonates and pediatric population. During recent decades there has been a change in the epidemiology of Candida infections, characterized by a progressive shift from a predominance of Candida albicans to non albicans Candida species. This study was undertaken to estimate the incidence of candidemia and determine species profile in the neonatal and pediatric intensive care units at a tertiary care hospital, Mumbai over a period of 20 months.

Method: The study was conducted in Department of Microbiology at a tertiary care Hospital, India. In a prospective analysis, a total of 2250 clinically suspected cases of sepsis in neonatal and pediatric intensive care unit were studied from April 2014 to November 2015. 1-3 ml of peripheral blood was collected aseptically from each case in BD BACTEC Peds Plus/F culture vials of an automated blood culture system and positive flashed samples showing budding yeast cells on Gram stain smear and/or culture positive for Candida spp were studied further. Candida speciation was done by germ tube test and microscopic morphology on cornmeal agar (CMA).

Results: A total of 113 Candida species were recovered from suspected cases of neonatal/pediatric sepsis over a period of 20 months (5.02%). Amongst these, Candida albicans constituted 6.19%, Candida glabrata 44.24%, Candida parapsilosis 11.5%, Candida tropicalis 9.73% and Candida krusei 0.88% while remaining 31 were non-albicans Candida spp (27.43%) which could not be speciated. Conclusion: Reporting of fungal blood stream infection and the spectrum of spp involved are essential measures in neonatal ICU and pediatric ICU in order to implement appropriate preventive and therapeutic strategies. In the present study, non Albicans Candida predominated among Candida isolates that was speciated. The striking feature of this study was the predominance of Candida glabrata among total number speciated which is a cause for concern.

Keywords: Candida species, Candidemia, Neonatal septicemia, Neonatal ICU

Introduction

Candida spp. are known to be the most common fungal pathogens isolated from blood cultures of neonates and paediatric population. They account for 9 to 13% of all blood stream isolates in neonatal intensive care units. 1, 2 During recent decades there has been a change in the epidemiology of Candida infections, characterized by a progressive shift from a predominance of Candida albicans to non albicans Candida species. Recently, non-albicans Candida has emerged as an important opportunistic pathogen, notably C. tropicalis, C. Glabrata and C. Parapsilosis. 3 This could be because of selection of lesser susceptible non-albicans species due to the frequent use of fluconazole. 4 Importance of Candida spp in the nursery and intensive care setup is increasingly being recognized. As there are differences between Candida albicans and non albicans Candida species in their antifungal susceptibility, patient profile etc, it has become imperative to speciate Candida isolates. This study was undertaken to estimate the incidence
of candidemia and determine species profile in the neonatal and paediatric intensive care units at a tertiary care hospital, Mumbai over a period of 20 months.

Methods

The study was conducted in Department of Microbiology at T.N.M.C & B.Y.L Nair Ch Hospital, Mumbai, India. This is a tertiary care, 2500 bedded hospital. In a prospective analysis, a total of 2250 clinically suspected cases of sepsis in neonatal and pediatric intensive care unit were studied. Institutional Ethical committee permission for the study was obtained. 1-3 ml of peripheral blood was collected aseptically from each case in BD BACTEC Peds Plus/F culture vials of an automated blood culture system (BACTEC 9120, Becton Dickinson, USA). Positive flashed samples showing budding yeast cells on Gram stain smear and/or culture positive for Candida spp were studied further. Candida speciation was done by germ tube test and microscopic morphology on cornmeal agar (CMA).

Results

A total of 113 Candida species were recovered from suspected cases of neonatal/ pediatric sepsis over a period of 20 months (5.02%). Amongst these, Candida albicans constituted 6.19%, Candida glabrata44.24%, Candida parapsilosis11.5%, Candida tropicalis9.73% and Candida krusei0.88% while remaining 31
were non Albicans Candida spp (27.43%) which could not be classified.

**Discussion**

Candidemia is a life-threatening fungal infection associated with mortality rates up to 38% and it also prolongs the duration of hospital stay. There is a growing trend of change with the emergence of non-albicans candida (NAC) species, it is a strain that increases mortality and antifungal drug resistance in severely ill patients. In the present study isolation rate of Candida from clinically suspected cases of sepsis in neonatal and pediatric intensive care unit in our study was 5.02% which is lower than other published reports. In a similar study by Jagdish Chander et al; on the epidemiology of Candida blood stream infection in a tertiary care hospital of North India isolated 5.79% candida species, this is similar to what we obtained in the present study. The most common Candida species isolated by them was C. tropicalis (40.8%) and in the present study, we found most common isolated species as C. glabrata in 44.2% of samples. The frequency of isolation C. glabrata by Jagdish Chander et al; was (18.5%). Studies have shown that the incidence of nosocomial candidemia and the proportion of bloodstream infection due to non-albican candida, particularly C. tropicalis, C. Glabrata and C. Parapsilosis have increased the change has been attributed mainly due to increased use of prophylactic antifungal agents in critically ill patients. The high rate of fungemia (22.8%) in neonates has been reported by a group and they also noted that 71.4% of neonates were colonized with yeasts within 24 hours of admission and colonization was more in LBW babies. Systemic candidias is in 3.2% of admissions in NICU has been reported by another study and C. tropicalis, C. Albicans and C. Guillermo were the commonest isolates.

In the present study, non Albicans Candida predominated among Candida isolates that was speciated. The striking feature of this study was the predominance of Candida glabrata among total number speciated which is a cause for concern. Candida glabrata candidemia in critically ill patients have been reported by Gupta et al; and Chakrabarty et al; Candida glabrata candidemia is difficult to manage and patients have high mortality as it shows relatively higher resistance to azoles especially fluconazole. Resistance to fluconazole is both intrinsic & acquired. Acquired resistance results from mutations that are selected by drug pressure. This necessitates the speciation and antifungal susceptibility testing of Candida isolates from cases of sepsis.

**Conclusion**

Reporting of fungal blood steam infection and the spectrum of spp involved are essential measures in neonatal ICU & pediatric ICU in order to implement appropriate preventive and therapeutic strategies. The present study indicates the importance of speciation of Candida isolates from sepsis cases.
